## INTRODUCTION

The determination of physical properties of liners, explosives, and propellants is important for the characterization of cook-off behavior, aging processes, and the mathematic modelling of the thermal responses of warheads and rocket motors.

The development of test hardware, data acquisition, and numerical methods for data reduction and analysis is of considerable importance. Thermal analysis techniques such as Differential Scanning Calorimetry (DSC), Thermogravimetric Analysis (TGA), and Differential Thermal Analysis (DTA) have traditionally been used to determine the thermal characteristics and decomposition kinetics of reactive substances.

As compared with other analytical techniques, thermal analysis has until recently received little attention in chemical research. This is primarily due to instrument insensitivity and the laborious task of manually reducing data. More sensitive techniques, usually spectroscopic in nature, were opted for in the determination of chemical kinetics.

There has recently been a resurgence of interest in thermal analysis due to the increased safety awareness of both the industrial and military sectors. This is due to the development of new materials for use in energy development, and for extraterrestrial and military applications.

Considerable activity has been generated in the area of the application of known numerical techniques to thermal analysis. This has been made possible with the development of new thermal analysis techniques, the availability of microprocessor-controlled analysis instrumentation, and the development of small computer technology for the acquisition and reduction of large quantities of data.

As a part of an ongoing process of upgrading the Naval Weapons Center's analytical capabilities, the Explosives Formulation Branch has written computer software to acquire and analyze data from laboratory instruments. These programs include routines to input digital data from interfaced digitizers and various numerical analysis and graphics subroutines to reduce, display, and analyze the data.

Chemical kinetics subroutines have been developed for nonisothermal DSC, isothermal DSC, and for TGA. This has been accomplished through the digitization of the analog outputs of the laboratory instrumentation which is achieved by interfacing with a Fluke 7600A scanning digital multimeter or Fluke 8520A digital multimeter. Transfer to the Hewlett-Packard 9845T computer is achieved via the IEEE-488 interface bus either by direct computer command or by use of service

request interrupts. The rate of data acquisition is programmed via command string to the microprocessor control units of the digital multimeters.

#### THEORETICAL BACKGROUND

Mathematical interpretation of thermodynamic data is accomplished through the application of the Gibbs-Helmholtz equation, usually stated as:

$$\frac{\partial \Delta G/T}{\partial (1/T)} = \Delta H$$

where  $G$  is the Gibbs free energy,  $H$  is the enthalpy, and  $T$  the absolute temperature. Kinetic data may be determined from the relationship  $\Delta G^\circ = -RT \ln K(T)$ ,  $K(T)$  being the equilibrium constant at temperature  $T$ . For a reaction such as  $A \rightleftharpoons B$ , the equilibrium constant may be written  $K(T) = k_2(T)/k_2^*(T)$  where  $k_2(T)$  is the rate of the forward reaction and  $k_2^*(T)$  is the rate of the reverse reaction.

Arrhenius first gave the expression for these rate constants as:

$$k_2(T) = Z \cdot \exp(-E^*/RT)$$

where  $Z$  is an experimentally determined rate constant with the dimensions mole/sec and  $E^*$  is the activation energy. The form of this equation was taken as a logical extension of the Gibbs-Helmholtz equation and is used presently in experimental determinations. Current interpretation of  $E^*$  is that of an energy barrier or depth of a potential well, and the factor  $\exp(-E^*/RT)$  is the probability per unit time that a molecule will penetrate the barrier.

From the Gibbs-Helmholtz equation, the temperature dependence of the equilibrium constant is given as:

$$\ln \frac{K(T_2)}{K(T_1)} = \frac{\Delta H}{R} \left[ \frac{1}{T_1} - \frac{1}{T_2} \right]$$

Unfortunately, when dealing with highly energetic materials, the chemical reactions are irreversible. The temperatures and pressures are not uniform and, in fact, have severe gradients throughout the material, presenting a problem in nonequilibrium thermodynamics. When dealing with small samples, temperature and pressure gradients are usually assumed to be negligible and a rate equation may be written for the reaction  $B \rightarrow \text{Products}$ :

$$\text{Rate} = \frac{dx}{dt} = k(T) \cdot f(X)$$

## NWC TP 6337

where  $X$  is the fraction of  $B$  that has reacted and  $f(X)$  is some function which depends upon the mechanism by which the reaction takes place.

For simple liquid and gaseous reactions,  $f(X)$  takes the form  $(1-X)^n$ , where  $n$  is referred to as the reaction order,  $n$  is usually 2 or less. A set of coupled reactions will yield fractional  $n$ 's while reactions which occur in the solid state via diffusion or nucleation mechanisms take on complex algebraic forms with  $n$  usually less than 1.

When looking at energetic materials,  $n=1$  works quite well in the higher temperature ranges where  $B \rightarrow$  Products is an accurate representation of the reactions taking place. However, at lower temperatures, nucleation reactions are present. They are dependent upon the surface free energy of the material which is affected by such factors as physical state, impurities, and method of preparation. Thus, a study of reaction rates at higher temperatures may give a somewhat limited view of the manner in which a material might behave.

For nonhomogeneous materials such as propellants, reaction rates are diffusion controlled and highly pressure-dependent. For materials of current interest,  $f(X)$  will stand for  $(1-X)$  for simple reactions and  $X(1-X)$  for the autocatalytic reactions which occur in many explosives.

For materials which melt with decomposition, complex kinetics occur in the initial stages of the decomposition reaction. Behavior beyond the exotherm maximum is usually more typical of the first order reaction,  $B_{(\text{liquid})} \rightarrow$  Products. The first stages of the decomposition process frequently draw the most interest in the thermal stability studies. Investigation of this behavior will give a more complete description of how a particular substance reacts.

## ANALYTICAL TECHNIQUES

### GENERAL

Ordinate data points are obtained by digitizing millivolt output from the instrumentation with the sensitivity of the instruments selectable by the operator. The analog output of the DSC represents energy absorption (endotherm) or release (exotherm) in units of millicalories per second. The TGA output represents milligrams.

Abscissa data points are obtained as time from the Real Time Clock interfaced to the HP 9845T computer. Temperature is obtained as the product of time and heating rate. Extremely accurate temperature

tracking has been achieved in the case of the DSC, while less favorable results have been obtained from the TGA. This is due to the heating rates deviating from programmed values. The problem has been eliminated by manually entering data into a separate computer program after the TGA run is complete.

Data points ( $X_j$ ,  $Y_j$ ) are curve-fitted using a precise continuous cubic polynominal, or cubic spline, algorithm. Ordinate values are represented as:

$$Y_j = \sum_{k=0}^3 M_{jk} X^k$$

where the coefficient matrix  $M$  is determined by demanding continuity of the polynominal and its first derivative at each data point.

Use of this algorithm allows facile differentiation and integration of the data curves and is relatively insensitive to noise in the instrumental output.

#### NONISOTHERMAL DSC

Graphics output of a DSC run of RDX Type II Class 5 is shown in Figure 1. Figure 2 is the data after a linear baseline correction has been made.

For a nonisothermal DSC run, the ordinant displacement  $dH/dt$  is given as:

$$D(t) = \Delta H \cdot \text{rate} = \Delta H \frac{dX}{dt} = \Delta H \cdot k(t)(1 - X)^n \quad (1)$$

where  $\Delta H$  is the total enthalpy change for the reaction, represented as the area  $A$ , under the displacement - temperature curve. Thus  $dX/dt = 1/A \cdot dH/dT$ . If this equation is integrated, the result is  $X = \Delta H_x(T)/A$  where  $\Delta H_x$  is the heat released due to the fraction  $X$  reacting. This is represented by the area  $a(T)$ , under the peak up until the temperature in question. Thus  $X(T) = a(T)/A$  may be determined graphically or by a numerical integration technique as is done by the computer program which has been developed (Figure 3).

Borchardt and Daniels<sup>1</sup> have shown that the rate constant may be expressed as:

$$k(T) = A^{n-1} \frac{dH(T)}{dt}$$

<sup>1</sup>Hans J. Brochardt and Farrington Daniels. "The Application of Differential Thermal Analysis to the Study of Reaction Kinetics," Journal of the American Chemical Society, Vol. 79, No. 4, July 1956, p. 41.

NWC TP 6337

Comparing the rate constants at two temperatures gives:

$$\frac{k(T_2)}{k(T_1)} = \frac{(dH/dt)(T_2)}{(dH/dt)(T_1)} \cdot \left[ \frac{A-a(T_1)}{A-a(T_2)} \right]^n$$

Since  $dH/dT$  is the ordinate deflection  $D(T)$ , and  $X = a(T)/A$ , this relation may be rewritten:

$$\frac{k(T_2)}{k(T_1)} = \frac{D(T_2)}{D(T_1)} \cdot \left[ \frac{1 - X(T_1)}{1 - X(T_2)} \right]^n$$

Assuming only one chemical reaction takes place,  $k(T)$  may be written:

$$k(T) = Z \cdot \exp(-E^*/RT)$$

and thus:

$$\frac{\exp(-E^*/RT_2)}{\exp(-E^*/RT_1)} = \exp\left[\frac{E^*}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right] = \frac{D(T_2)}{D(T_1)} \cdot \left[ \frac{1 - X(T_2)}{1 - X(T_1)} \right]^n$$

and:

$$-E^*\left[\frac{1}{T_2} - \frac{1}{T_1}\right] = R \ln\left[\frac{D(T_2)}{D(T_1)}\right] + nR \ln\left[\frac{1 - X(T_1)}{1 - X(T_2)}\right]$$

Thus the activation energy may be calculated from ordinate displacement and partial areas. In fact, for closely spaced data points, the last term approaches zero.<sup>2</sup>

The frequency factor  $Z$ , and thus the rate constant may be calculated using partial areas and known values. With  $\phi$  as the heating rate:

$$\frac{dX(r)}{dt} = \phi \cdot \frac{dX(r)}{dT} = Z \cdot \exp[-E^*/RT(r)] \left[1 - \frac{a(r)}{A}\right]$$

In the computer implementation of this method,  $E^*$  is calculated from a linear least squares (linear regression) algorithm which fits the curve of  $\ln D$  versus  $1/T$  (Figure 4).

<sup>2</sup> Jen Chiu. "Dynamic Differential Calorimetric Technique for Measuring Heat of Polymerization," in Proceedings of the Second Symposium on Analytical Calorimetry, ed. by Roger S. Porter, New York Plenum, 1970, p. 171-183.

Figure 5 shows a plot of the reaction rate versus fraction decomposed. Ideally, the plot should provide some idea of the algebraic form of the rate equation, with a straight line indicating a first order reaction. For an autocatalytic reaction, a straight line would result from plotting rate versus  $X(1-X)$ . In the case of solids, there are several processes occurring simultaneously and a clear and precise interpretation of this plot would be difficult to achieve. In a homogeneous liquid, such as is present to the right of the exotherm maximum in the case of RDX, a portion may be represented by

RDX (Liquid)  $\rightarrow$  Products:

$$\text{Rate} = k(T)(1 - X) \quad (2)$$

and appears as a virtually linear portion of the curve. This portion may be selected for determination of kinetics for the first order reaction of Equation 2.

Kissinger<sup>3</sup> has devised a method based upon variable heating rates to determine the activation energy. This method is independent of reaction order and should give an accurate value for  $E^*$  assuming that only one chemical reaction is taking place at a time. The basic equation is given as:

$$\frac{d(\ln \phi/T_m)}{d(1/T)} = -E^*/R$$

where  $T_m$  is the temperature at which the maximum exotherm or endotherm occurs. A plot of  $\ln \phi/T_m$  versus  $1/T_m$  from several runs will have slope  $-E^*/R$ .

#### ISOTHERMAL DSC

The software developed for nonisothermal DSC has been modified to allow for the treatment of the isothermal case.

Because the temperature is constant in an isothermal DSC, the equation:

$$\frac{dx}{dt} = \lim_{t_2-t_1 \rightarrow 0} \frac{a(t_2) - a(t_1)}{A \cdot (t_2 - t_1)} = k(T) \cdot f(x) \quad (3)$$

may be solved directly for  $k(T)$ .

---

<sup>3</sup>Homer E. Kissinger. "Reaction Kinetics in Differential Thermal Analysis," Analytical Chemistry, Vol. 29, June 1957, p. 1702.

For closely spaced data points,  $dX/dt$  is reasonably approximated as  $\Delta a/\Delta t \cdot A$ . A plot of  $\Delta a/A/\Delta t$  versus  $a/A$  will indicate the nature of  $f(X)$ , and  $k$  is calculated directly by linear regression analysis for the linear portion of this curve when first order kinetics are observed. One could plot rate versus different algebraic forms of  $f(X)$  to see if a straight line results. Again,  $f(X)$  would be expected to take the form  $(1-X)$  or  $X(1-X)$  for explosives.<sup>†</sup> Figures 6 to 9 are graphic output examples of this program and Tables 1 and 2 provide examples of numeric outputs.

The activation energy is calculated by plotting the values of  $k(T)$  obtained at several temperatures versus  $1/T$ . The slope of this plot is  $E^*/R$ .

Previous isothermal kinetic determinations have used the portion of data to the right of the exothermic peak. By integrating Equation 3, a plot of fraction unreacted versus time should have the form:

$$1 - X = \exp [-k(T) \cdot t] \quad (4)$$

for a first order reaction (Figure 10).<sup>4</sup>

From Equation 1, the ordinate displacement  $D(t)$  is given as  $\Delta H \cdot k(T) \cdot (1-x)$ . For a first order reaction:

$$D(t) = \Delta H \frac{dx}{dt} = \Delta H \cdot k(T) \cdot (1 - x)$$

Substituting Equation 4 for  $(1-x)$  gives:

$$D(t) = \Delta H \cdot k(T) \cdot \exp [-k(T) \cdot t]$$

or

$$\ln[D(t)] = \ln[\Delta H \cdot k(T)] - k(T) \cdot t$$

---

<sup>†</sup>Jamey and Rodgers. Los Alamos Scientific Laboratory, Private Communication.

"Ray N. Rogers. "Differential Scanning Calorimetric Determination of Kinetics Constants of Systems That Melt With Decomposition," Thermochimica ACTA, Vol. 3, 1972, p. 437-447.

Thus a plot of  $\ln D$  versus time should have slope  $k(T)$  for a first order reaction.<sup>5</sup> Figure 11 shows the plot of  $\ln D$  versus time for RDX Class 5. The linear portion of this curve was used for determination of first order kinetics for  $\text{RDX}(l) \rightarrow \text{Products}$ .

From the form of Equation 1, it is seen that  $\ln D = n \ln(1-a) + \text{constants}$ , so a plot of  $\ln D$  versus  $\ln(1-a)$  should yield the reaction order  $n$ . Figure 12 represents this plot. Calculation of the slope in the region from which kinetic data were calculated gives a value of 1.05, which agrees with the assumption of a first order reaction.

Both the partial area technique and the old technique of plotting  $\ln D$  versus  $t$  give essentially the same answer in the region chosen. The partial area technique is more dynamic in that the fraction of material reacted can be calculated at any point. Thus, if some reaction mechanism is hypothesized, it may be verified with actual experimental numbers.

#### THERMOGRAVIMETRIC ANALYSIS

While the DSC data are useful for describing the thermodynamics of a system, TGA is necessary for correlating weight loss with temperature. For reactions of the type solid  $\rightarrow$  gas, TGA may be used for kinetic determinations. The fraction  $X$ , given as  $X = M-m/M$ ,  $M$  = original mass, and the reaction rate  $dx/dt$  may be taken directly from the TGA data.

Numerical analysis for TGA data is the same as that for nonisothermal DSC. Because the temperature rise rate in the TGA instrument is nonlinear, temperature must be calculated after the run is completed. Temperature/mass data are then manually entered into the computer. Temperature is accurately determined by entering millivolt values from strip chart output and converting to temperature values using a standard National Bureau of Standards interpolating polynomial. Data for RDX Class 5 is shown in Table 3 and is plotted in Figures 13 through 15.

This program was developed primarily to investigate the decomposition of rocket motor liners where time, temperature, and mass values are important. If only mass and temperature are needed, the software is easily modified to allow entry of approximately ten times the number of data points. The acquisition of computer compatible thermogravimetric equipment will also allow acquisition of more data points when all three reference points are required.

## CONCLUSIONS

The acquisition and analysis of large amounts of data with a digital computer has opened a new field in the area of thermal analysis. Plotting and numerical analysis software allow the data to be reduced in a fraction of the time previously needed and permit use of a larger number of data points.

In addition, fast integrating algorithms allow use of partial area techniques which will prove to be very influential in future analytical procedures.

The successful application of these computer techniques in the determination of isothermal kinetics should prove extremely useful in determining the cook-off hazards from aging studies and understanding cook-off behavior.

NOMENCLATURE

A	Total Area
a	Partial Area
D(t)	Ordinate Deflection
E*	Activation Energy
f(x)	Algebraic Function of Fraction Reaction
G	Gibbs Free Energy
H	Enthalpy
K(T)	Equilibrium Constant
k(T)	Rate Constant
R	Universal Gas Constant
T	Temperature
T <sub>m</sub>	Temperature of Maximum Exotherm
t	Time
X	Fraction Reacted
Z	Preexponential Factor in Arrhenius Equation
Φ	Heating Rate

INITIAL DISTRIBUTION

4 Naval Air Systems Command
